U.S. NAVY REGIONAL CLIMATIC STUDY OF THE PERSIAN GULF AND THE NORTHERN ARABIAN SEA

The U.S. Navy Regional Climatic Study of The Persian Gulf and The Northern Arabian Sea was prepared for the Commander, Naval Oceanography Command (CNO) by the Officer in Charge, Naval Oceanography Command Detachment, Asheville, North Carolina. The work was performed in Asheville at the National Oceanic and Atmospheric Administration's (NOAA) National Climatic Data Center (NCDC). The surface marine and coastal station statistics presented in this study were made possible through programs designed at the NCDC and funded primarily by CNO in support of the U.S. Navy's continuing marine climatology requirements.

Special acknowledgement is given to the following meteorologists of the NCDC's Global Climate Laboratory (GCL): William A. Brower, Jr., for serving as project leader and climatic analyst; Phala L. Franks, for performing the computer processing and editing of marine data; M. Lawrence Nicodemus and William O. Brown, for production of the Station Climatic Summaries; and Michael J. Changery, for performing an editorial evaluation of the text, isopleth analyses, and graphics products. Specific acknowledgment is also made to the GCL's Ronald G. Baldwin, computer programmer/analyst, for production of the computer-generated graphic presentations; and to meteorological technicians Charles W. Thomason for editing the isopleth analyses, and Michael G. Burgin and Scott J. Miller of GCL, and David A. McKittrick of General Electric Contract Services, for their drafting skills in preparation of this publication for printing.

Geographical Coverage

This climatic study covers the Persian Gulf and the Northern Arabian Sea located within 14° and 31° north latitudes and 47° and 75° east longitudes. Figure 1 shows the marine area and 13 coastal stations for which climatic statistics are presented. This study area is the first of three areas to be published based on a single analysis effort of a much larger marine area which includes the Red Sea, Gulf of Aden, Persian Gulf, Gulf of Oman, Arabian Sea, and Western Indian Ocean waters north of Madagascar. The total marine analysis area is bounded by 10° south and 35° north latitudes and 25° and 75° east longitudes (excluding 10S-10N, 65-75E). An analysis was performed on the entire marine area to permit continuity between the three study areas.

Climatic Data and Summaries

Surface marine statistics are presented on monthly charts in the form of isopleths, tables, and roses. Statistics include the monthly means or percent frequency of occurrence of threshold values for wind, visibility, clouds, precipitation, air and sea surface temperatures, ocean waves, and surface currents. The marine statistics for the total analysis area, except for ocean currents, are based on approximately 3.8 million hourly observations taken from the NCDC's Tape Data Family (TDF) 1129. These observations were collected by ships of various registry frequenting the marine area over the period 1854-1990.

Many of the ships' observations are presently transmitted over the Global Telecommunications System, captured and archived. Other observations are digitized from ship log forms by various participating members of the World Meteorological Organization, and exchanged under international agreement among the various maritime nations of the world. Although data for this study date from 1854, most of the observations have been collected in the past 40 years, which is significant because recent observations contain more elements than pre-1949 reports. The density of observations within the analysis area is greatest along major shipping routes along the near-coastal waters of the Arabian Peninsula, and the Indian Ocean route between the Gulf of Aden and southern tip of India.

The TDF-1129 data were subjected to thorough computer and visual quality control to eliminate duplicate observations and exclude questionable elements detected during internal consistency and extreme value checks. The edited data were computer summarized and plotted by one-degree quadrangles and

Figure 1. Station location and geographical coverage

subjectively analyzed by meteorologists to produce isopleth maps. Subjective adjustments were made to the analyses when data biases or insufficient observations were evident. Consistency checks were also made in the sets of monthly patterns for each element and among elements, as well as comparative checks with other marine atlases and publications.

Computer graphics tables of visibility and wave heights, and roses of winds and ocean currents are also presented by one-degree quadrangles on monthly charts. The legends on the charts contain detailed instructions on how to read the graphics. The graphics represent the objective compilation of available data. These data were not adjusted for suspected biases (low observation count, heavy weighting of observations taken during relatively short time intervals, biases in coding of observations from various source decks, etc.); hence, differences may be found when comparing the graphical data with the isopleth analyses. The total number of observations for a given quadrangle should always be considered when interpreting the data because there may not be a sufficient number for the calculation of climatically representative statistics.

Station Climatic Summaries (SCS) are presented in tables for the 13 coastal stations shown in Figure 1 and Table 1. Hourly (telecommunications) data for the years 1973-90 were processed for each of the stations. The SCS tables for these 13 stations were taken from the April 1992 version of the International Station Meteorological Climate Summary (ISMCS) file containing 900 stations. The ISMCS file, which is presently being updated and is to contain about 1,400 stations, is a joint production by the Naval Oceanography Command Detachment (NOCD), the United States Air Force Environmental Technical Applications Center (ETAC), and the National Climatic Data Center (NCDC) located at the Federal Climate Complex in Asheville, NC. The summaries for the 13 stations are based on data from the edited digital files of the ETAC.

TABLE 1. Climatic Summary Stations

WHO NO.	STATION NAME	LATITUDE	LONGITUDE
40582	Kuwait Intl AP, Kuwait	29-13N	47-59E
40858	Bushire, Iran	28-59N	50-50E
40875	Bandar Abbas, Iran	27-13N	56-22E
41150	Bahrain Intl AP, Bahrain	26-16N	50-39E
41170	Doha, Qatar	25-15N	51-34E

41316	Salalah, Oman	17-02N	54-05E
41780	Karachi, Pakistan	24-54N	67-08E
43003	Bombay, India	19-07N	72-51E

A word of caution. The intent of this atlas presentation is to gather and present existing data on climatological conditions within the marine and near coastal areas of the Persian Gulf and North Arabian Sea. The data are presented without discussion and interpretation. Given the information presented in the introductory text, legend descriptions on all charts, and numbers of observations displayed with the graphics presentations, the user should be able to assess the degree of statistical confidence in the presented climatology for a given month and location. The climatological statistics for the 13 coastal stations are presented to afford a better climatological picture of the coastal area. Differences, however, may be found when comparing the station tabular data with the marine statistics.

PHYSICAL FEATURES

The waters in this marine climatic study of the Persian Gulf and the Northern Arabian Sea within 14°-31°N and 47°-75°E touch the shores of 11 countries: Yemen, Oman, United Arab Emirates, Qatar, Saudi Arabia, Bahrain,

Kuwait, Iraq, Iran, Pakistan, and India. (All but India are within the Moslem world.) The influence of these waters upon the adjacent lands is restricted by the prevailing pressure patterns and the mountainous topography of the surrounding lands so that aridity and continentality characterize most of the study area.

The Persian Gulf-Gulf of Oman waters are a northwestern extension of the Arabian Sea. The Persian Gulf itself forms a great 530 nautical mile (nm) concave curve running southeasterly from the mouth of Iraq's Euphrates River Delta to the Strait of Hormuz, and averages about 130-150nm wide and 65-200 feet deep. The Persian Gulf, on entering the Strait at Dubayy, quickly narrows to less than 30nm and deepens to a maximum depth of 300 feet. Here, the Gulf of Oman begins and extends southeastward beyond the Strait some 280nm as it rapidly increases in width to 200nm with depths greater than 6,000 feet before joining the Arabian Sea. The generally accepted boundary between the Gulf of Oman and the Arabian Sea is an imaginary line drawn from the Iran-Pakistan border to the eastern most point of Oman at Ras al Hadd. Figure 2 provides some general bathymetry information.

Narrow coastal plains bordering the marine study area are surrounded by vast deserts and wastelands to the west and south and by Iran's Zagros Mountains to the north. Salt marshes at the northwestern end of the Persian Gulf extend from Kuwait to the Iranian coast near 30°N, 50°E, and inland from 15 to 70nm. Desert lies beyond the salt marshes. The southern shore is nearly flat from Iraq southeastward to the Oman Peninsula. Terrain in Saudi Arabia inland of the shoreline is a mixture of sand dunes, wadis (dry washes), and low gravel ridges. Sand dune fields are concentrated within 50nm of the coast from Kuwait to Az Zahran near 26°N, 50°E; south of Az Zahran these fields extend inland from 75 to 200nm. Elevations rise slowly inland to about 1,700 feet. South of Abu Zaby, and extending southwest to the mountains of extreme eastern Yemen, is the "Empty Quarter," an area of sand dunes and ridges with almost no permanent human inhabitants. Sand ridges mix with the sand dune fields from the Oman Peninsula south and eastward to within 50 to 75nm of the mountain range along the Gulf of Oman-Arabian Sea coast. Salt flats are common within 15nm of the coast along the entire southern gulf shore. A range of mountains runs along the coast the length of Oman from the Strait of Hormuz to 20nm west of Ras al Hadd. Elevations range from 5,000 to nearly 10,000 feet along the ridge, with elevations dropping to less than 1,700 west of this mountainous spine. A narrow coastal plain backed by hilly, sometimes mountainous, terrain runs along the entire Oman-Arabian Sea coast. Maximum elevations reach 2,500 feet.

Terrain on the Iranian, or northern, shore of the Persian Gulf is in sharp contrast to the rest of the region. Numerous mountain ranges, oriented parallel to the Persian Gulf-Gulf of Oman, front a narrow (20 to 40nm) coastal plain from the Tigris-Euphrates delta southeastward for 105nm to just southeast of Bushire. Southeast and east of this point to the Strait of Hormuz, the major ranges rise almost immediately inland from the coast. The highest mountains are inland of the northwestern half of the Gulf, with peaks ranging from 11,000 to more than 14,000 feet. Southwestward from the Strait of Hormuz to the Iran-Pakistan border, mountain ranges form the coast and rise rapidly, exceeding 5,000 feet within 40nm of the coast and 10,000 feet within 90nm. Figure 1 provides some general topography information.

GENERAL CIRCULATION AND CLIMATE

The climate of the marine study area is one of sharp contrasts between marine and continental controls. As a result of the seasonal variation in incoming solar radiation and the differential heating and cooling of Asia to the north, Africa to the west, and the Indian Ocean to the south, a winter to summer reversal in pressure systems and winds creates a monsoon climate over Southern Asia and the Arabian Sea. Solar radiation and the low heat capacity of the Asian land mass results in the fall formation and spring decay of the extensive cold Siberian High centered near 50°N, 95°E, and the spring formation and fall decay of the warm Pakistani Low centered near 10°N, 65°E. The mean sea level pressure charts for January and July in Figure 4 illustrate the general monsoon circulation.

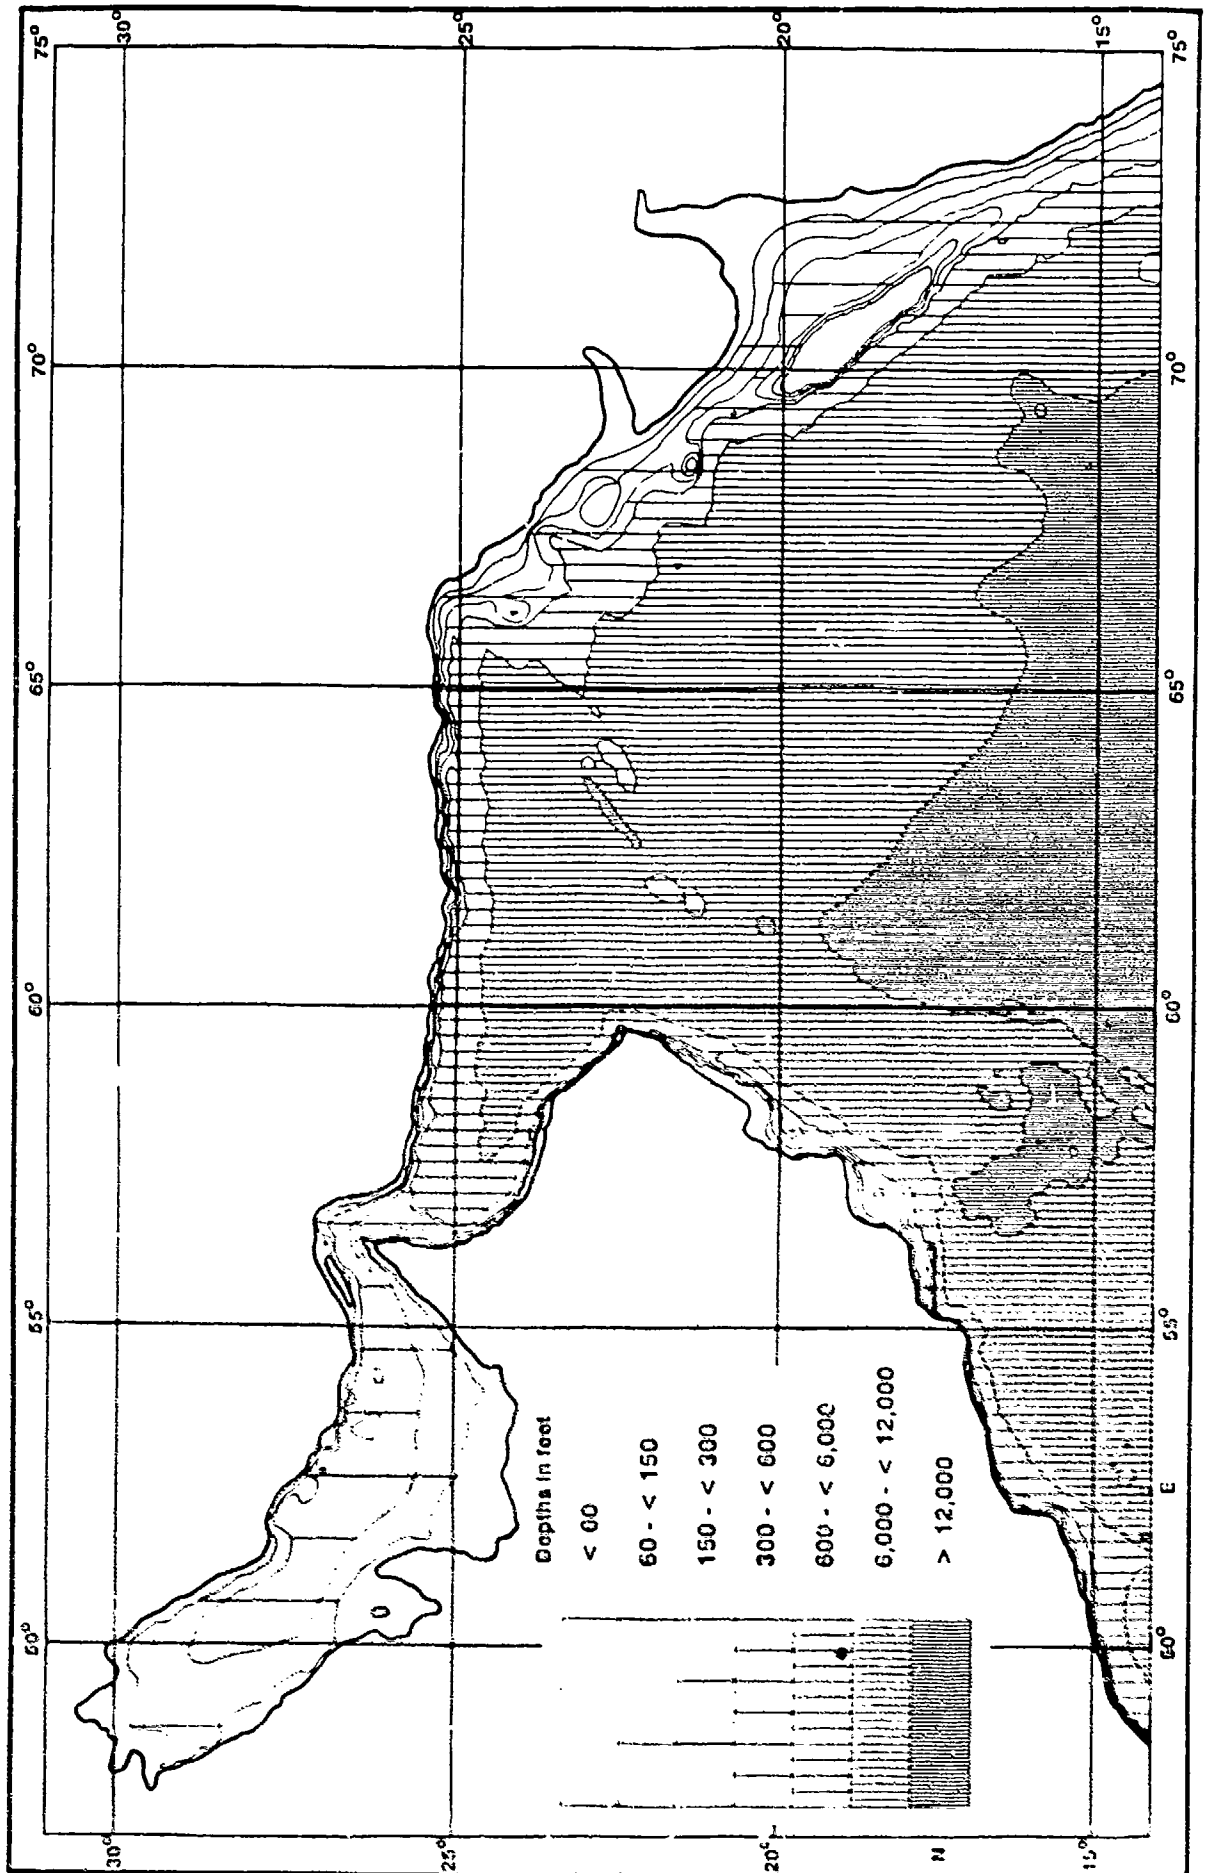

Figure 2. Bathymetry

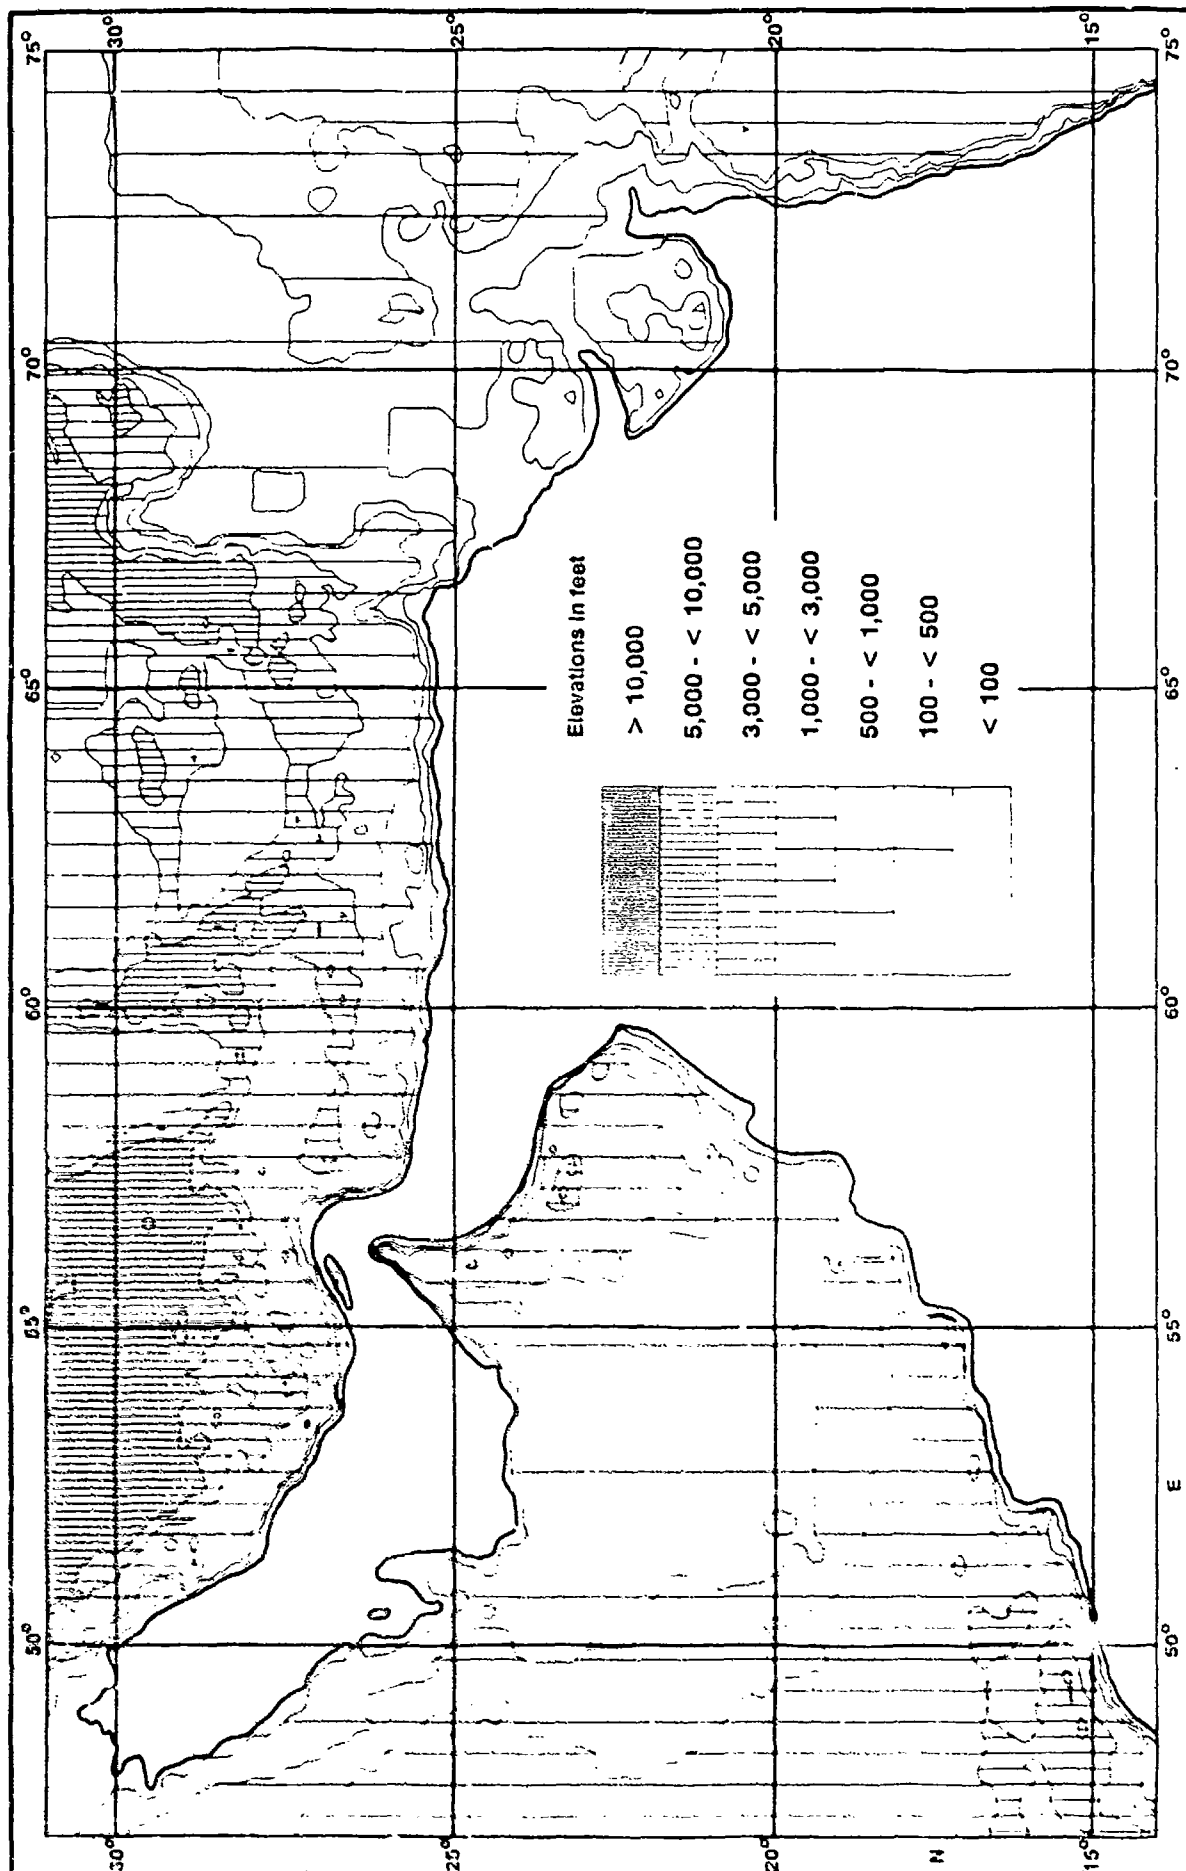

Figure 3. Topography

Figure 4. Sea-level pressure (millibars)

This monsoon climate is characterized by two distinct monsoon seasons separated by two short (30-45 day) transition periods. The winter northeast monsoon, present from November through March, is dominated by northeasterly low-level flow controlled by the Siberian High and a deep thermal low over Australia. In April and May this northeasterly circulation rapidly breaks down and, during May to September, is replaced by the Pakistani Low and its associated secondary lows in Saudi Arabia and Saharan Africa. The Intertropical Convergence Zone (ITCZ) moves rapidly north into the intensifying heat lows and the southern hemisphere southeasterly trade winds cross the Equator, recurve to reinforce the summer southwest monsoon flow across the Arabian Sea into India. During this time, the Indian Ocean High moves northwestward and intensifies. In October and November, the Pakistani Low collapses as days become shorter. Cooling over Siberian Russia reestablishes the Siberian High, and the ITCZ migrates southward once again. Low-level northeasterly flow is reestablished over Southern Asia and the Arabian Sea and the cycle repeats itself.

The continental influence is strengthened by the tropical latitudes of southern Asia as well as by the height and extent of the massive east to west continental mountain systems. The peninsula extensions of Asia into the latitudes of the subtropical anticyclonic belt are a factor in the intensity of the summer heating and hence the strength of the southwest monsoon, whereas the zonally oriented mountain systems reduce the strength of the northeast monsoon by largely containing the Siberian High in winter. Other continental features favoring the monsoon flow are the northeast to southwest orientation and the generally high elevations of the coasts of Arabia and East Africa; these features tend to channel the summer monsoon toward the Pakistani Low and the winter monsoon toward the African Equatorial Low.

Within the study area, the Persian Gulf, Gulf of Oman, and western Arabian Sea experience predominantly continental airflow resulting in relatively low humidities and large temperature contrasts throughout the year. Because of the landlocked nature of the Persian Gulf (and Red Sea), the influx of hot, dry air from the surrounding deserts, and the high incidence of solar radiation with few clouds, these waters constitute the hottest sea surfaces in the world. Continental influences are also important in the northern and eastern Arabian Sea, just off the Asiatic mainland, under the influence of the cool, dry offshore airflow of the Northern Hemisphere winter. During summer, however, maritime influences are dominant in this area of the Arabian Sea.

The winter northeast monsoon prevails in the Arabian Sea to slightly south of the equator. Never as vigorous as the monsoon of summer, the winter monsoon is strongest and most constant over the central and western Arabian Sea south of 20°N. The main source of relatively cooler air arrives over the area from Europe by way of the Mediterranean Sea and Persian Gulf. However, the lowest temperatures occur when cold, continental air flows out of the wintertime Siberian High through the western passes of the Hindu Kush Mountains (35°N, 71°E). The warming of the polar continental air as it moves southward soon transforms into tropical continental over the peninsulas and tropical maritime over the Arabian Sea. Weather in this air is generally fine, with clear skies, low humidities, and minimal rainfall. North of 20°N, and especially in the Persian and Oman Gulfs, clear, sunny weather is less likely. The wind variability at the head of the Arabian Sea and in the Gulf of Oman and the Persian Gulf reflects the continental influence of land and sea breezes, topographic channelling, and the movement of western depressions through the Persian Gulf and along the southern Iran-Pakistani coast. The frequent eastward passage of weak lows along the mountainous coasts cause variable winds, increased cloudiness, and sometimes rain. Squalls, dust storms, or occasional thunderstorms may accompany the deeper depressions or rapidly moving cold fronts.

The summer southwest monsoon is much stronger and deeper, and chiefly of Southern Hemisphere maritime origin rather than Northern Hemisphere continental origin. This airflow is one of the most persistent in the world. Since the southwest monsoon has a long trajectory over water, it brings an abundance of moisture to the continent. Southwesterly flow has a direct affect on the Arabian Sea coast of Oman, the Gulf of Oman, the Arabian Sea coast of Iran, southern Pakistan, and India. It is accompanied by more remarkable weather events, including strong winds, exceptional rainfall

amounts, and, on rare occasions, tropical storms. As this humid, unstable air stream develops in June, cloud and rainfall amounts increase rapidly. Where onshore winds encounter mountainous terrain, as along the west coast of India, the onset of cloud buildup and resultant rainfall has a dramatic suddenness. As the season progresses, cloud and rainfall frequencies remain high, but spells of fair weather intervene between monsoon surges. Strong upwelling along and just off the Oman Arabian coast assists in the maintenance of the Southwest Monsoon.

Intense extratropical cyclones rarely occur in the Arabian Sea, although depressions from the eastern Mediterranean, and some originating in the Sahara and western Arabia, do pass through the Persian Gulf during the Northern Hemisphere winter, retaining much of their original strength. They are frequently accompanied by gales, and thunderstorms are sometimes associated with their cold fronts.

The normal winter pressure gradient is slight over the Persian Gulf which lies between the Siberian High and the extension of the Atlantic High. The comparatively warm temperature of the water causes a shallow low pressure to be apparent over the gulf. Over most of the gulf, northwesterly winds are most frequent, but near the Strait of Hormuz where the gulf is oriented northeast to southwest, the winds are often westerly and southwesterly. This prevailing northwesterly gulf wind, known as the Shamal, occurs in the Persian Gulf and over its immediate land areas following passage of cold fronts southeastward. The strong summer Shamal is rarely associated with storms but is brought about by a deepening of the Pakistani Low. Unlike the winter Shamal, the changes in speed of the summer Shamal are gradual and more predictable. The Shamal is strongest and most persistent from early June until mid-July. During this period, sometimes called the 40-day Shamal or great Shamal, winds may occasionally reach gale force and bring clouds of dust and sand from the desert to the gulf. During August, there is a marked decrease in speed of the Shamal, but it continues as the dominant wind. During periods of strong Shamal the air is usually hot and dry, and the sky is cloudless. The Shamal produces the most widespread hazardous weather known to the Persian Gulf region.

The winds of the Gulf of Oman are distinct from those of the Persian Gulf. Instead of being dominated by the Shamal, the winds are variable and generally light during winter, and mostly under the influence of the southwest monsoon in summer. Southwesterly winds are most prominent at the eastern end of the gulf, but at the center of the gulf they are deflected to the south or southeast, and at the western end the winds are variable.

Over the Arabian Sea as a whole, gales are rare and generally occur less than 1% of the time. However, strong local winds may be encountered in some coastal areas, the most notable example being the Belat which blows off the southern Arabian coast during the northeast monsoon. The Belat is a well-developed northerly land breeze which may reach gale force for periods of a few minutes or several hours. This wind generally begins and ends quite abruptly and is frequently associated with sandstorms over land. It may persist for several days.

Tropical storms, occasionally of hurricane intensity, usually form in the eastern Arabian Sea within 10-15°N, 70-75°E and migrate slowly northwestward. All tropical storms that enter the study area disintegrate over land or before reaching the 50th meridian. Such storms occur at an average of one per year, during the transitional seasons of autumn and spring.

The ocean surface currents in the Arabian Sea are driven primarily by the seasonal winter northeast monsoon and summer southwest winds. However, because of oceanographic and physiographic factors, the exact monthly extent of the seasonal current patterns varies somewhat at different locations. The configuration of India's coastline sets the currents in the eastern Arabian Sea northwest in winter and southeast in summer during the monsoon seasons. Figure 5 shows the January and July general surface current pattern for the Arabian Sea during the peak of the winter northeast and summer southwest monsoon winds. The surface current pattern for the transitional months is variable or a weakened version of one of the monsoonal patterns. Currents in the Persian Gulf and the Gulf of Oman set westward and northwestward along

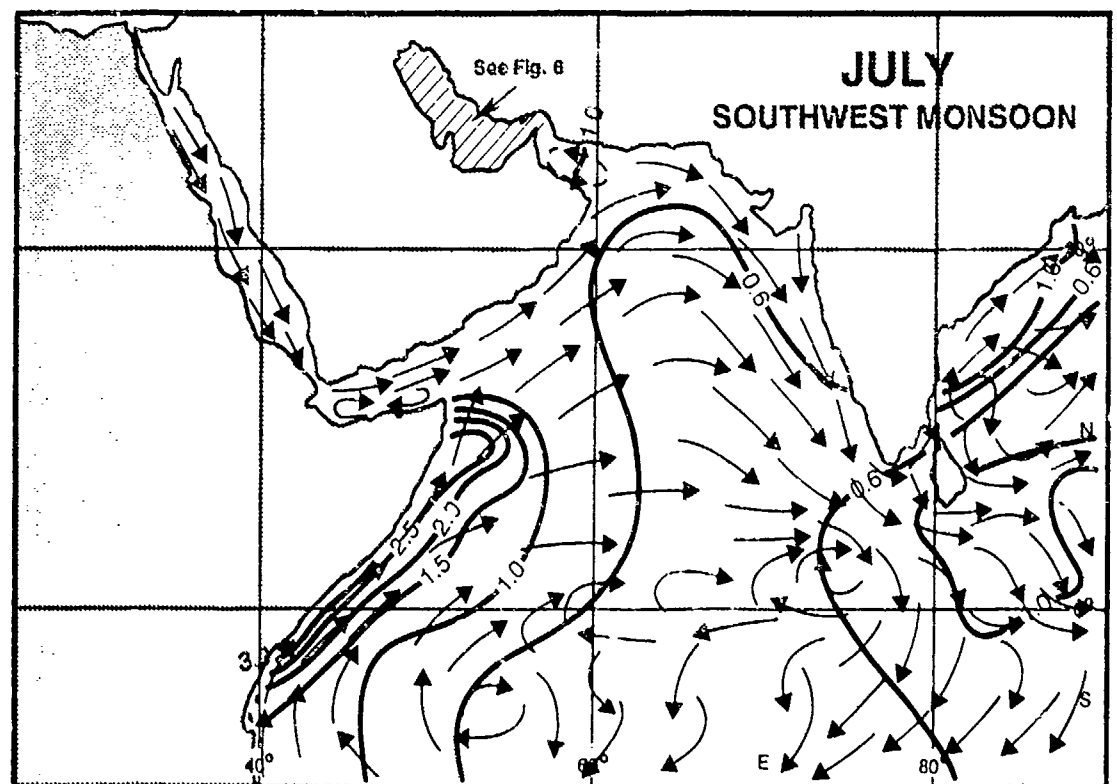

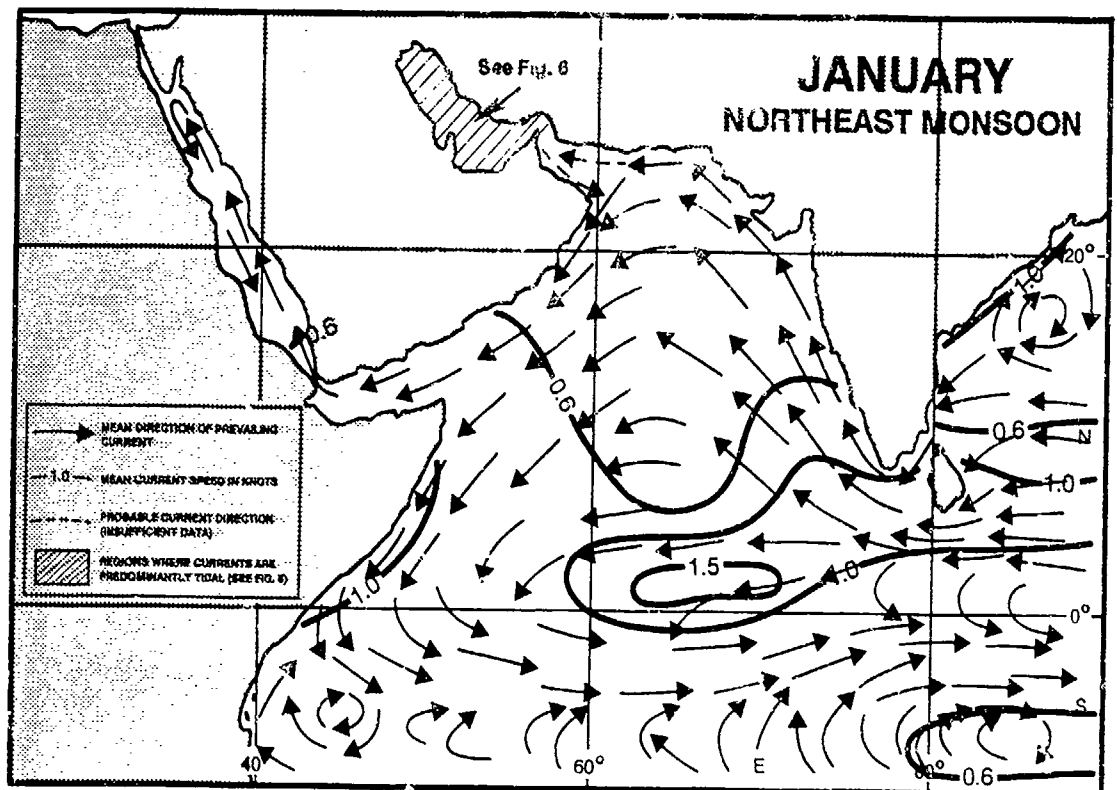

Figure 5. Surface currents

the north shores and southeastward along the south shores. Tidal influences cause considerable variability in the currents in the Persian Gulf and in the Strait of Hormuz. Figure 6 shows the flood and ebb tidal currents for the gulf and strait.

Marine Climatological Elements

Precipitation

Of the elements recorded in the marine data base, precipitation is the one most subject to error in both the way it is observed and the way it is interpreted. For example, it is often inferred in the literature that ships often try to avoid foul weather and thereby bias the data towards fair weather with fewer precipitation observations. Elms (1986) compared the Volunteer Observing Ship (VOS) and buoys, finding little evidence that "fair weather bias" is a serious problem for most applications of marine climatic data. With the introduction, in 1982, of a present weather indicator (i) to the International Ship Synoptic code FM13-VII, users have to be careful not to bias the data, especially that from between January 1982 and March 1985 when the indicator was inadvertently left out of the international data exchange format.

Assessing oceanic precipitation is always a major problem because transit ships are unable to take quantitative measurements. A number of studies have been conducted in an effort to predict precipitation amounts, or rates of fall based on estimates derived from readings from satellites (Rao, et al., 1976). For the monthly isopleth presentations of percent frequency of precipitation, the present weather codes 20-27 (precipitation within the past hour) were included with codes 50 through 99 to compute the percent frequency of precipitation in an effort to correct an apparent observational bias. This brings the frequencies more in line with results obtained from ocean weather station observations, the most reliable bench-mark for the open ocean.

Air Temperature

Air temperature is one of the elements most frequently observed by mariners. It should be noted that on many ships the heating effect of the ship's structure has a tendency to produce higher than actual ambient air temperature readings because of instrument exposure (Folland, et al., 1984; Wright, 1986). This is especially true under calm, sunny conditions. Therefore, some ship temperature observations have a warm bias; however, the aggregate is relatively representative after erroneous outliers have been eliminated and the numerous nighttime observations and unbiased daytime observations are included. Also, true extremes are rarely captured since continuous observations are not made at most ocean locations. It is highly unlikely that a ship-of-opportunity would be taking its synoptic weather observations at the exact time that an extreme was occurring. Monthly isopleths of mean air temperature are presented.

Sea-Surface Temperature

Sea-surface temperatures are recorded with fairly high frequency in marine observations. The principle methods for sampling are with ship water-intake thermometers and by reading the temperature of sea water retrieved with buckets. Even though the two methods can produce slightly different results (Barnett, 1984), the data can be used with considerable confidence when examining the long-term means. Monthly isopleths of mean sea-surface temperature are presented.

Surface Winds

Surface wind is one of the most commonly observed elements. Many of the observations from the NCDC data base are visual observations based on the roughness of the sea. In recent years, more ships acquired anemometers and reported measured winds. Prior to 1963, many observed wind speeds were recorded in the Beaufort scale; such estimates have proven to be quite reliable and can be used with a high degree of confidence. Five sets of

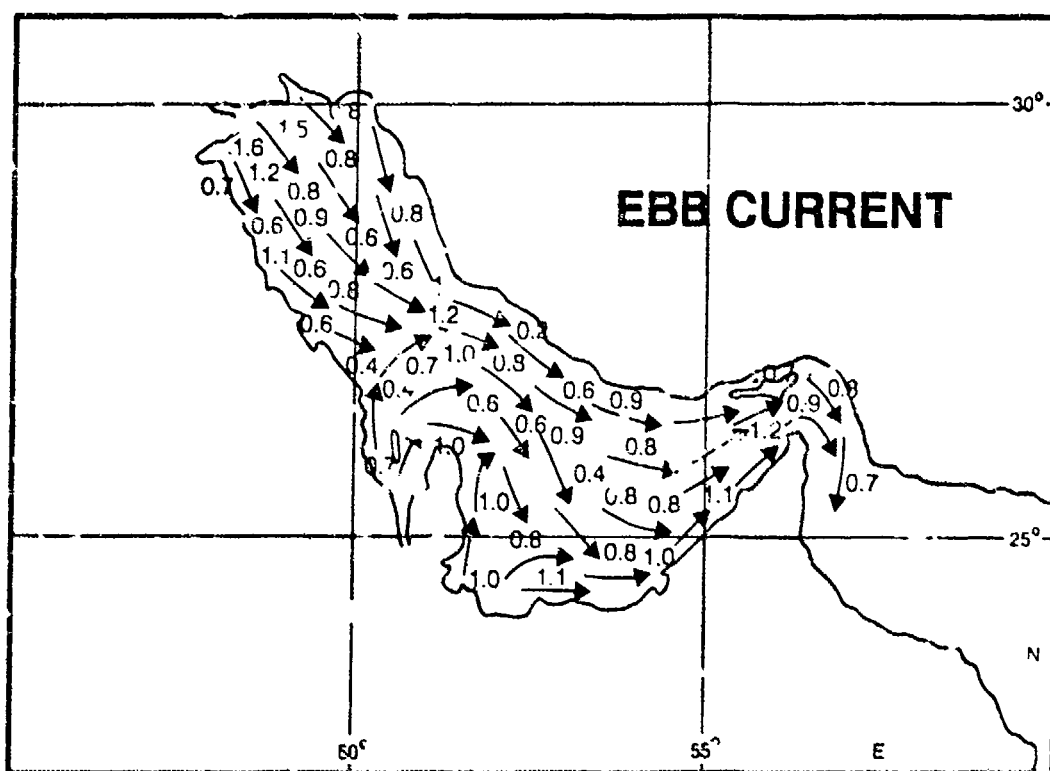

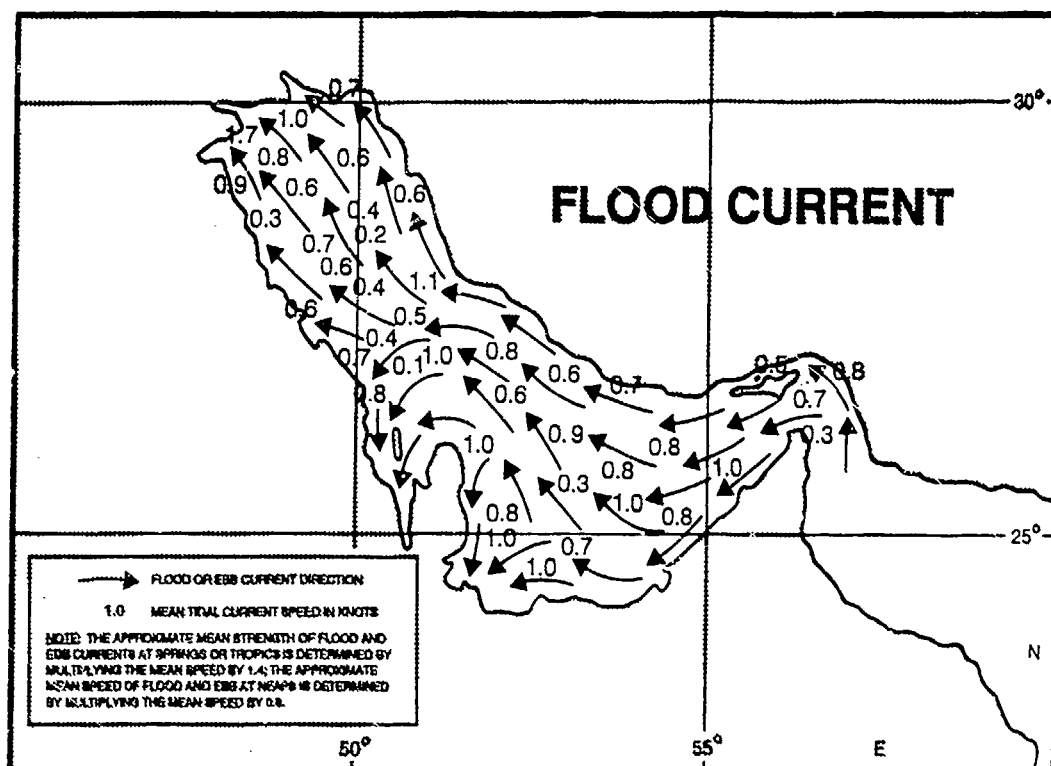

Figure 6. Tidal currents - Persian Gulf

monthly wind speed isopleths are presented: the scalar mean speed and the percent frequency of winds less than 11 knots, from 11 to 21 knots, from 22 to 33 knots, and greater than or equal to 34 knots. Also given are monthly wind roses for one degree quadrangles.

Visibility

Visibilities are difficult to measure at sea because of the lack of distance reference points. Climatically, many low visibility observations are probably missed because the observer is too busy with other duties (a contrasting form of fair weather bias). However, the coarseness of visibility (code) intervals helps to minimize the problem, thereby permitting the summarized monthly tabulations of visibility data presented by one-degree quadrangles to be relatively consistent.

Clouds

A survey of the cloud data (total and low cloud amount) from the surface marine observations data base shows that the number of total cloud reports are significantly greater than that of low cloud amounts. This is because many of the early marine observations contain only total cloud amount. For the two monthly presentations (total cloud amount less than/equal to 2/8, and low cloud amount greater than/equal to 5/8), only those observations reporting both total and low cloud amounts were summarized. This helps eliminate problems introduced as a result of different size data sets (n-count). The use of satellite data helps to bolster confidence in the total cloud analyses because they show fairly close agreement with those observed from the surface (U.S. Department of Commerce and United States Air Force, 1971).

Ceiling and Visibility

Aircraft-type ceilings are not available from marine observations. The ceilings are estimated from the height of the lowest cloud when low clouds cover more than half the sky. When the sky is totally obscured by rain, fog, dust, or other phenomena, the total obscuration is considered a ceiling with a height of zero. Monthly percent frequency isopleth charts are presented for mid-range ceiling and visibility (ceiling less than 1000 feet and/or visibility less than 5 nautical miles; ceiling less than 8000 feet and/or visibility less than 10 nautical miles) and low-range ceiling and visibility (ceiling less than 300 feet and/or visibility less than 1 nautical mile; ceiling less than 600 feet and/or visibility less than 2 nautical miles).

Wave-Heights

Wave-heights have been recorded in consistent quantitative code since the late 1940's. The reluctance of many observers to take wave observations in the earlier years and the difficulty in estimating waves, especially in confused seas, make wave observations one of the least commonly observed elements. The observations are also subject to biases. Generally, the heights are too low, the periods too short, and the sea-swell discrimination poor (Quayle, 1980). The data in this study have not been adjusted for the suspected biases, but were processed through a quality control procedure wherein an internal check was made between wind speed and sea-height. The data were also matrix-arrayed and apparent erroneous outlier data values were deleted from both the sea and swell data. Wave-height presentations include isopleth maps showing percent frequencies of wave-heights greater than or equal to 3 feet and greater than or equal to 8 feet. In addition, wave-height tables by quadrangle show frequencies by six wave-height categories. In these presentations, the higher of the sea or swell was selected for summarization. If heights are equal, the wave with the longer period was selected.

T = TRACE AMOUNTS (< .05 INCHES)

N = MEAN NO. DAYS < 5 DAYS

P = PRESSURE ALTITUDE IN TENS OF FEET (I.E., 50 = 500 FEET)

S = NAVY STATIONS REPORTED HAIL AS SNOWFALL

H = STATIONS REPORTED HAIL AS SNOWFALL FOR THE PERIOD JULY 1948-DECEMBER 1955

P = THE PREDOMINANT SKY CONDITION, OR PRECIPITATION IN EXCESS OF THE INDICATED AMOUNT.

V = VISIBILITY IS NOT CONSIDERED, MIST INCLUDED WHEN REPORTED.

S = ANNUAL TOTALS MAY DIFFER FROM THE SUM OF THE MONTHLY VALUES BECAUSE OF ROUNDING.

T = 24 HOUR MAXIMUM PRECIPITATION AND SNOWFALL ARE DAILY TOTAL VALUES (MID-NIGHT TO MID-NIGHT TOTALS).

***** = INDICATES DATA NOT AVAILABLE.

I = INSUFFICIENT NUMBER OF AVAILABLE OBSERVATIONS FOR COMPUTATION.
